The present invention relates generally to methods and systems for controlling the operating frequency of a microprocessor in a digital computer and more particularly to a method and system for controlling the operating frequency of a microprocessor to reduce the number of interrupts in an application running on the microprocessor. In a digital computer, it is often necessary to switch the operating frequency of a microprocessor from a first frequency to a second frequency. It is known in the art to switch the operating frequency of a microprocessor by stopping the application, entering a frequency control routine and changing the operating frequency. This method of switching operating frequencies consumes valuable system resources. More importantly, this method of switching operating frequencies introduces additional latency to the application. While this application will be described in terms of the microprocessor operating at a specific frequency in response to an interrupt, it should be recognized that this is only one application in which an operating frequency switching algorithm can be employed. It should also be recognized that other applications, such as real time applications in which interrupts are not acceptable, can also utilize a frequency switching algorithm. It is also known in the art to utilize a fixed clock frequency to create multiple, independent microprocessors on a single integrated circuit, commonly referred to

as a multi-chip module (MCM). While these independent microprocessors may be useful in many applications, the microprocessors may not be able to operate at different frequencies due to fabrication variations, power supply variations, and temperature variations. Thus, a need exists for a method and system for controlling the operating frequency of a microprocessor which can be used to reduce the number of interrupts in an application. It is therefore an object of the present invention to 2edc1e01e8
